<ロト < 回 ト < 回 ト < 亘 ト < 亘 ト < 亘 ト 三 の Q () Introduction to Econometrics: ECON 418-518

Definition 1: Decision Tree

A decision tree is a non-parametric regression and classification algorithm that partitions the feature space into a series of rectangles and then fits a simple model.

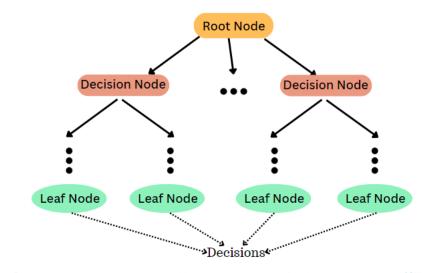

- Decision trees for:
 - Regression are called regression trees.
 - Classification are called *classification trees*.
- A "simple model" is just the sample average.

Regression Tree Prediction

Definition 2: Regression Tree Prediction

The prediction using a regression tree t for a feature vector x is given by the average outcome across observations in the leaf node (region) R_m that x lands in:

$$\widehat{f}_t(\boldsymbol{x}) = \frac{1}{|R_m|} \sum_{i \in R_m} y_i.$$

Classification Tree Prediction

Definition 3: Classification Tree Prediction

The prediction using a classification tree t for a feature vector x is given by a majority vote across observations in the leaf node (region) R_m that x lands in:

$$\widehat{f_t}(\boldsymbol{x}) = rgmax_{c \in \{1,2,\dots,C\}} \left[\sum_{i \in R_m} \mathbb{1}(y_i = c) \right].$$

CART Algorithm

Question 1: CART Algorithm

How are the split point and split variables determined?

Answer to Question 1

The Classification and Regression Tree (CART) algorithm.

CART Algorithm

Definition 4: CART Algorithm

The CART algorithm follows these steps:

1. Start at the root node.

▲□▶ ▲□▶ ▲□▶ ▲□▶ □ ののの

CART Algorithm

Definition 4: CART Algorithm

The CART algorithm follows these steps:

- 1. Start at the root node.
- 2. Select the best split (determine the best split point and best split variable).

CART Algorithm

Definition 4: CART Algorithm

The CART algorithm follows these steps:

- 1. Start at the root node.
- 2. Select the best split (determine the best split point and best split variable).
- 3. Partition the data based on the split.

CART Algorithm

Definition 4: CART Algorithm

The CART algorithm follows these steps:

- 1. Start at the root node.
- 2. Select the best split (determine the best split point and best split variable).
- 3. Partition the data based on the split.
- 4. Repeat steps 2 and 3 until some stopping criteria is met (such as depth of the tree).

CART Algorithm

Definition 4: CART Algorithm

The CART algorithm follows these steps:

- 1. Start at the root node.
- 2. Select the best split (determine the best split point and best split variable).
- 3. Partition the data based on the split.
- 4. Repeat steps 2 and 3 until some stopping criteria is met (such as depth of the tree).
- 5. Prune the tree.
- Tree depth is a hyperparameter that needs to be tuned.
- Tree pruning is a technique used to reduce the depth of the tree to avoid overfitting.

Cost Complexity Pruning

Definition 5: Cost Complexity Pruning

Cost complexity pruning is a technique used to prune a decision tree to avoid overfitting by considering a trade-off between the complexity of the tree and its fit to the training data.

- *Pruning* is the process by which we try to remove unnecessary leaf nodes from the original tree to reduce overfitting.
- The goal is to find the subtree T_{α} of the original T that generalizes better.
 - α penalizes decision tree for being too deep (similar to λ in ridge and lasso regression).

Decision Trees Pros

Property 1: Decision Trees Pros

- 1. Simple to understand and interpret.
- 2. Requires little data preprocessing (no need for normalization or scaling).
- 3. Can handle both numerical and categorical data.
- 4. Capable of capturing non-linear relationships.

Random Forests

Decision Trees Cons

Property 2: Decision Trees Cons

- 1. Prone to overfitting (high variance).
- 2. Can be unstable (small changes in data can lead to different trees).

Introduction to Econometrics: ECON 418-518

3

Random Forest

Definition 6: Random Forest

A random forest is a non-parametric regression and classification algorithm that combines the predictions of T decision trees to form a final prediction.

- This final prediction is the sample average of predictions produced by the *T* trees for regression or the majority vote for classification.
- A random forest is an example of *bagging* (bootstrap aggregating) *ensemble learning* method.

The "Random" in Random Forests

Question 2: The "Random" in Random Forests

Why are random forests "random"?

Answer to Question 2

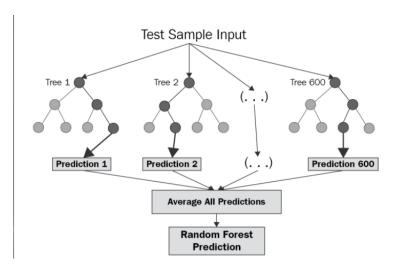

- 1. Each decision tree t = 1, ..., T is fit using a different *bootstrapped* sample.
- 2. Each decision tree uses only a subset of the total possible features for splitting.
- *Bagging* greatly helps to reduce the high variance of learning algorithms like decision trees.

Random Forest Regression Prediction

Definition 13: Random Forest Regression Prediction

The prediction using a random forest regression for a feature vector \boldsymbol{x} is given by the average prediction produced by the T trees in the random forest:

$$\widehat{f}(\boldsymbol{x}) = rac{1}{T} \sum_{t=1}^{T} \widehat{f}_t(\boldsymbol{x}).$$

イロト イボト イヨト イヨト

Random Forest Classification Prediction

Definition 14: Random Forest Classification Prediction

The prediction using a classification random forest for a feature vector \boldsymbol{x} is given by a majority vote across the T trees in the random forest:

$$\widehat{f}(\boldsymbol{x}) = rgmax_{c \in \{1,...,C\}} \sum_{t=1}^{T} \mathbb{1}\left(\widehat{f}_t(\boldsymbol{x}) = c\right).$$
